

METHOD AND APPARATUS FOR MONITORING THE QUALITY OF LUBRICANT

Background of the Invention

5 The present invention relates to a method and to an apparatus
for monitoring the quality of lubricating oil (hereinafter also designated
merely as lubricant) that is in a gear mechanism or a machine and that
contains effective materials or substances.

10 In machinery and equipment construction, and in particular in
gear mechanism technology, the quality of the lubricant is an important
influencing factor that determines the availability, the reliability and the
safety of the overall drive train or the lubricated structural components.
Oil-soluble effective substances, such as, for example, various
extreme-pressure and anti-wear additives, are added to mineral oils,
15 mineral oil products, or synthetic oils to improve the lubricating effect or
the chemical properties. Differences in the quality in the various
lubricants represents a competitive criterion. Experience in the
maintenance of gear mechanisms has shown that even the best
lubricants age and must be exchanged. In this connection, one
20 changes over in stages from the scheduled oil change intervals more to
oil change periods that are a function of the condition of the oil or

lubricant. The criterion is the classic oil analysis by means of which the physical and chemical parameters of the lubricant are analyzed.

Unfortunately, clearly measurable criteria that can be a measure of when the quality of an oil is insufficient, do not yet exist. For this reason, for example in the wind power industry, it is a standard and required by regulation, that for wind power units the towers must be regularly climbed, oil samples taken, and the oil quality subsequently determined in a laboratory. If individual parameters of the oil become impaired, the lubricant is exchanged already for safety reasons. To be able to determine the suitable point in time for changing the oil, these analyses require a well-equipped analysis laboratory, as well as a precise withdrawal of sample. Determined are the viscosity, the pH, the quantity of foreign particles, and their composition. The properties can be determined only with very expensive analysis equipment, and can be evaluated only by specialists.

Immediate indications of possible danger to the gear mechanism due to an inadequate quality of the aged oil are possible only in the final stage of the lubricant. A large number of oil-changing criteria can be found in the technical literature; these criteria in part contradict one another.

It is therefore an object of the present invention to provide a method and an apparatus that, on site, enables a rapid and reliable

monitoring of the quality of the lubricant in a gear mechanism or machine.

Brief Description of the Drawing

5 This object, and other objects and advantages of the present invention, will appear more clearly from the following specification in conjunction with the single schematic drawing, which shows a diagrammatic view of one exemplary embodiment of an inventive apparatus for monitoring the lubricant quality.

10

Summary of the Invention

 The inventive method of monitoring the quality of lubricant includes the steps of withdrawing from a gear mechanism or machine a sample of the lubricant or of vapor that escapes from the lubricant, conveying a sample of the vapor escaping from the lubricant to an ion mobility spectrometer, analyzing materials of the sample that are present in a vapor phase above the lubricant, and comparing a change of content and type of analyzed materials in the sample to predetermined materials in a vapor phase of virgin lubricant, and using such comparison as an actual condition for the aging of the lubricant.

20

 The inventive apparatus for monitoring the quality of the lubricant comprises a sample withdrawal line connected to the gear

mechanism or machine, an ion mobility spectrometer connected to the sample withdrawal line, and an analysis unit connected to the ion mobility spectrometer.

5 The inventive approach is based on the recognition by the inventor of the fact that the lubricants can be differentiated by their odor depending upon origin, age and composition. The odor results, among other things, from the effective materials and their decomposition products that are added to the heavy-duty lubricants to improve the properties thereof. If the content of the effective materials in the
10 lubricant is reduced during operation due to aging, the composition of the vapor phase over the lubricant also changes. Pursuant to the present invention, it is now proposed to analyze the materials present in the vapor phase above the lubricant with a measuring device, especially with an ion mobility spectrometer. An ion mobility
15 spectrometer is known, for example, from DE 195 15 270 A, and is used for the analysis of trace gases. Within the context of the present invention, the ion mobility spectroscopy is used to analyze the materials present in the vapor phase above the oil and to compare the results with comparison values that are found in virgin lubricants. From
20 the change of the content of volatile components relative to the starting condition, a conclusion is drawn of the changed quality of the lubricant. The type of determination of the state of the quality of the oil with the

aid of the ion mobility spectrometer is reliable and rapid, can be carried out on site, and can be remotely controlled. The measurement results can be transmitted to any desired location, thereby enabling a remote monitoring.

5 Further specific features of the present invention will be described in detail subsequently.

Description of Preferred Embodiments

10 Referring now to the drawing in detail, the gear mechanism 1 or a machine is surrounded by a housing 2 that is filled to a prescribed level with lubricating oil or lubricant to lubricate the rotating parts within the housing 2. The gear mechanism 1 is preferably installed in a unit, for example in a wind power unit, that is not constantly monitored by
15 personnel.

The housing 2 of the gear mechanism 1 is provided with a sample withdrawal line 3 by means of which a quantity of lubricant sample, or of oil vapor, which forms above the oil bath in the housing 2, is withdrawn. If oil vapor is withdrawn, the sample withdrawal line 3
20 can be connected to the oil-venting device 4 by means of which a pressure equalization is provided for the gear mechanism 1. The

sample withdrawal line 3 can also be connected to a different connector that is mounted on the housing 2 above the oil bath.

The sample withdrawal line 3 is guided to a measuring device, especially an ion mobility spectrometer 5, which comprises a reaction chamber 6 and a drift chamber 7. The reaction chamber 6 is provided with a sample inlet 8 and an outlet 9, and accommodates an ionization source 10. The drift chamber 7 is provided on the inner side with drift rings 11 that are connected in pairs and are connected with a high voltage direct current source. As a result, an axial electrostatic field is built up in the drift chamber 7.

The reaction chamber 6 is separated from the drift chamber 7 by a switching or contact grid 12 that in principle is provided with a plurality of electrically conductive elements that are connected in pairs and are connected to a power source. The elements are separated from one another by openings or perforations. At that end opposite the contact grid 12, an ion detector 13 is disposed in the drift chamber 7. The ion detector 13 is connected via an amplifier with an analysis unit 14, which in turn can be connected with a remote monitoring site.

In the reaction chamber 6, the molecules contained in the entering sample stream are ionized with the aid of the ionization source 10. By applying a specified voltage pattern, the contact grid 12 is alternatingly open or blocked for the ions. In the open phase, the ions

enter the drift chamber 7, where they are separated and migrate in the direction toward the ion detector 13 against a drift gas, for example air, nitrogen or the like, that has been supplied via the drift gas inlet 15. The ions that strike or encounter the ion detector 13 cause, at that location, a signal stream that is stored and analyzed in the analysis unit 14. Depending upon the content or the type of material that is to be tested, different spectra result in the analysis unit 14.

The materials contained in the oil vapor are analyzed pursuant to the process principle described above, whereby depending upon the content of the type of materials, a specific spectrum is given that is indicated in the analysis unit 14. Since various effective materials or substances are added to a lubricant, the decomposition products that are contained in the oil vapor and are clearly shown in the analyzed spectrum represent a significant index for the condition of the lubricant. If the appearance of the spectra (actual condition) changes in comparison with the starting condition (desired condition) of the virgin lubricant, it is possible to determine with the aid of the pertaining spectra how the additive of the lubricant that is important for operation has decomposed, and if the lubricant has aged or even contains water.

The measurement results obtained by the ion mobility spectrometer 5 with regard to the change in the content and the type of the materials contained in the oil vapor are utilized in the analysis unit

14 as the actual condition for the aging of the lubricant relative to virgin lubricant. When a prescribed threshold is reached or exceeded in the analysis unit 14, a warning signal is generated, for example for the maintenance personnel. The analyzed measurement results can also be transmitted to the maintenance personnel via known telediagnostic technology.

As a result of the analysis, an alarm can be triggered in a control room 16. The measurement results can also be conveyed to a remote data transmission means 17, e.g. telemetry, or the internet, and can be recalled in a remote monitoring station 18. If from the analyzed and transmitted measurement results there is indicated a critical condition with regard to the quality of the lubricant, there is a requirement for action, which is indicated to the maintenance personnel by a warning signal. Then, if necessary, fresh effective material is added to the aged lubricant, or the lubricant is exchanged.

The specification incorporates by reference the disclosure of German priority document 102 35 612.2 filed August 2, 2002.

The present invention is, of course, in no way restricted to the specific disclosure of the specification and drawing, but also encompasses any modifications within the scope of the appended claims.
